This post will look at a few different ways of attempting to simplify decision tree representation and, ultimately, interpretability. All code is in Python, with Scikit-learn being used for the decision tree modeling.

[KNIME Analytics Platform for Data Wranglers: Basics](#)

By [Matthew Mayo](#), KDnuggets.

When discussing classifiers, decision trees are often thought of as easily interpretable models when compared to numerous more complex classifiers, especially those of the blackbox variety. And this is generally true.

This is **especially** true of rather comparatively simple models created from simple data. This is much-less true of complex decision trees crafted from large amounts of (high-dimensional) data. Even otherwise straightforward decision trees which are of great depth and/or breadth, consisting of heavy branching, can be difficult to trace.

Concise, textual representations of decision trees can often nicely summarize decision tree models. Additionally, certain textual representations can have further use beyond their summary capabilities. For example, automatically generating functions with the ability to classify future data by passing instances to such functions may be of use in particular scenarios. But let's not get off course -- interpretability is the goal of what we are discussing here.

This post will look at a few different ways of attempting to simplify decision tree representation and, ultimately, interpretability. All code is in Python, with Scikit-learn being used for the decision tree modeling.

Building a Classifier

First off, let's use my favorite dataset to build a simple decision tree in Python using [Scikit-learn's decision tree classifier](#), specifying information gain as the criterion and otherwise using defaults. Since we aren't concerned with classifying unseen instances in this post, we won't bother with splitting our data, and instead just construct a classifier using the dataset in its entirety.

```
1 import numpy as np
2 from sklearn import datasets
3 from sklearn import tree
4
5 # Load iris
6 iris = datasets.load_iris()
7 X = iris.data
8 y = iris.target
9
10 # Build decision tree classifier
11 dt = tree.DecisionTreeClassifier(criterion='entropy')
12 dt.fit(X, y)
```

dt-hacks-1.py hosted with ♥ by GitHub

[view raw](#)

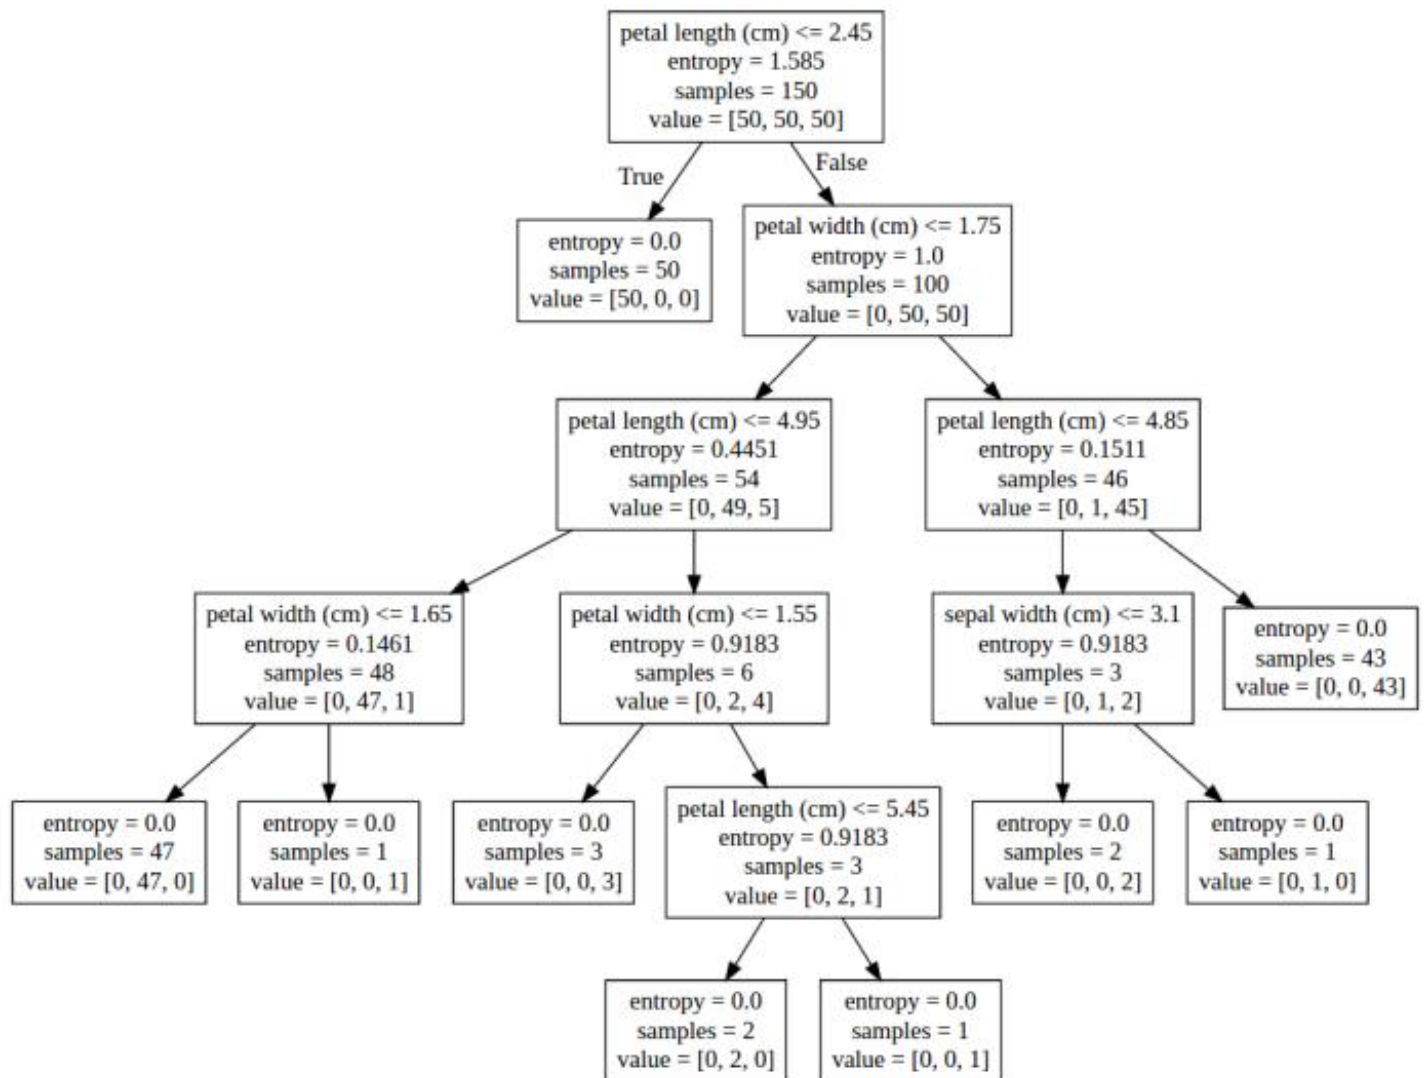

One of the easiest ways to interpret a decision tree is visually, accomplished with Scikit-learn using these few lines of code:

```
1 dotfile = open("dt.dot", 'w')
2 tree.export_graphviz(dt, out_file=dotfile, feature_names=iris.feature_names)
3 dotfile.close()
```

dt-hacks-2.py hosted with ♥ by GitHub

[view raw](#)

Copying the contents of the created file ('dt.dot' in our example) to a [graphviz rendering agent](#), we get the following representation of our decision tree:

Representing the Model as a Function

As stated in the outset of this post, we will look at a couple of different ways for textually representing decision trees.

The first is representing the decision tree model [as a function](#).

```

1  from sklearn.tree import _tree
2
3  def tree_to_code(tree, feature_names):
4
5      '''
6      Outputs a decision tree model as a Python function
7
8      Parameters:
9      -----
10     tree: decision tree model
11
12     The decision tree to represent as a function

```

```

12     feature_names: list
13         The feature names of the dataset used for building the decision tree
14     '''
15
16     tree_ = tree.tree_
17     feature_name = [
18         feature_names[i] if i != _tree.TREE_UNDEFINED else "undefined!"
19         for i in tree_.feature
20     ]
21     print "def tree({}):".format(", ".join(feature_names))
22
23     def recurse(node, depth):
24         indent = " " * depth
25         if tree_.feature[node] != _tree.TREE_UNDEFINED:
26             name = feature_name[node]
27             threshold = tree_.threshold[node]
28             print "{}if {} <= {}:".format(indent, name, threshold)
29             recurse(tree_.children_left[node], depth + 1)
30             print "{}else: # if {} > {}".format(indent, name, threshold)
31             recurse(tree_.children_right[node], depth + 1)
32         else:
33             print "{}return {}".format(indent, tree_.value[node])
34
35     recurse(0, 1)

```

dt-hacks-3.py hosted with ♥ by GitHub

[view raw](#)

Let's call this function and see the results:

```
tree_to_code(dt, list(iris.feature_names))
```

```

def tree(sepal length (cm), sepal width (cm), petal length (cm), petal width (cm)):
    if petal length (cm) <= 2.45000004768:
        return [[ 50.  0.  0.]]
    else: # if petal length (cm) > 2.45000004768
        if petal width (cm) <= 1.75:
            if petal length (cm) <= 4.94999980927:
                if petal width (cm) <= 1.65000009537:
                    return [[ 0. 47.  0.]]
                else: # if petal width (cm) > 1.65000009537
                    return [[ 0.  0.  1.]]
            else: # if petal length (cm) > 4.94999980927
                if petal width (cm) <= 1.54999995232:
                    return [[ 0.  0.  3.]]
                else: # if petal width (cm) > 1.54999995232
                    if petal length (cm) <= 5.44999980927:
                        return [[ 0.  2.  0.]]
                    else: # if petal length (cm) > 5.44999980927
                        return [[ 0.  0.  1.]]
        else: # if petal width (cm) > 1.75
            if petal length (cm) <= 4.85000038147:
                if sepal length (cm) <= 5.94999980927:
                    return [[ 0.  1.  0.]]
                else: # if sepal length (cm) > 5.94999980927
                    return [[ 0.  0.  2.]]
            else: # if petal length (cm) > 4.85000038147
                return [[ 0.  0. 43.]]

```

Interesting. Let's see if we can improve interpretability by stripping away some of the "functionality," provided it is not required.

Representing the Model as Pseudocode

Next, [a slight reworking of the above code](#) results in the promised goal of this post's title: a set of decision rules for representing a decision tree, in slightly less-Pythony pseudocode.

```

1  def tree_to_pseudo(tree, feature_names):
2
3      '''
4      Outputs a decision tree model as if/then pseudocode
5
6      Parameters:
7      -----
8      tree: decision tree model
9          The decision tree to represent as pseudocode
10     feature_names: list
11         The feature names of the dataset used for building the decision tree
12     '''
13
14     left = tree.tree_.children_left
15     right = tree.tree_.children_right
16     threshold = tree.tree_.threshold
17     features = [feature_names[i] for i in tree.tree_.feature]
18     value = tree.tree_.value
19
20     def recurse(left, right, threshold, features, node, depth=0):
21         indent = " " * depth
22         if (threshold[node] != -2):
23             print indent, "if ( " + features[node] + " <= " + str(threshold[node]) + " ) {"
24             if left[node] != -1:
25                 recurse (left, right, threshold, features, left[node], depth+1)
26             print indent, "} else {"
27             if right[node] != -1:
28                 recurse (left, right, threshold, features, right[node], depth+1)
29             print indent, "}"
30         else:
31             print indent, "return " + str(value[node])
32
33     recurse(left, right, threshold, features, 0)

```

dt-hacks-4.py hosted with ♥ by GitHub

[view raw](#)

Let's test this function:

```
tree_to_pseudo(dt, list(iris.feature_names))
```

```

if ( petal length (cm) <= 2.45000004768 ) {
    return [[ 50.  0.  0.]]
} else {
    if ( petal width (cm) <= 1.75 ) {
        if ( petal length (cm) <= 4.94999980927 ) {
            if ( petal width (cm) <= 1.65000009537 ) {
                return [[ 0.  47.  0.]]
            } else {
                return [[ 0.  0.  1.]]
            }
        } else {

```

```
if ( petal width (cm) <= 1.54999995232 ) {
    return [[ 0.  0.  3.]]
} else {
    if ( petal length (cm) <= 5.44999980927 ) {
        return [[ 0.  2.  0.]]
    } else {
        return [[ 0.  0.  1.]]
    }
}
}
} else {
    if ( petal length (cm) <= 4.85000038147 ) {
        if ( sepal length (cm) <= 5.94999980927 ) {
            return [[ 0.  1.  0.]]
        } else {
            return [[ 0.  0.  2.]]
        }
    } else {
        return [[ 0.  0.  43.]]
    }
}
}
```

This looks pretty good as well, and -- in my computer science-trained mind -- the use of well-placed C-style braces makes this a bit more legible than the previous attempt.

These gems have made me want to modify code to get to true decision rules, which I plan on playing with after finishing this post. If I get anywhere of note, I will return here and post my findings.
